1. A doctor and a resident are reading scans and classifying tumors. Given 10 scans, the doctor classifies 9 of them correctly, while the resident classifies 6 correctly.

- (a) Give the formula for probability and odds. Explain their difference.

$$\text{probability} = \frac{\#events}{\#subjects}$$

$$\text{Odds} = \frac{\frac{\#events}{\#subjects}}{\frac{\#non-events}{\#subjects}} = \frac{\text{probability}}{(1-\text{probability})} = \frac{\#events}{\#non-events}$$

The difference is that the value of probability is between 0 and 1, while the value of odds ranges from 0 to infinity, and in the event that non-event doesn't exist, the odds is not defined.

- (b) What is the odds of the doctor reading the scan correctly? What is the odds of the resident? What is the odds ratio of the doctor reading the scan correctly compared to the resident?

Ans:

the odds of the doctor reading the scan correctly: $\text{Odds}(\text{doctor}) = \frac{9}{1} = 9$

the odds of the resident reading the scan correctly: $\text{Odds}(\text{resident}) = \frac{6}{4} = 1.5$

Odds ratio between doctor and resident: $\frac{9}{1.5} = 6$

- (c) What is a logit and how can it be used to derive a linear model to express the exponent of odds?

Ans:

The logit L of a probability p is defined as $L = \ln \frac{p}{1-p}$. To derive the linear model: $\ln \frac{p}{1-p} = \ln(p) - \ln(1-p) = Wx + b$

- (d) Using the model, what is the odds ratio of making a correct reading as a doctor compared to a resident?

Ans:

$$\text{Odds-ratio} = \frac{\text{Odds}(\text{Doc})}{\text{Odds}(\text{Res})} = 6 = \exp(\ln(\frac{p_D}{1-p_D})) - \exp(\ln(\frac{p_R}{1-p_R})) = \exp((\ln(p_D) - \ln(1-p_D)) - (\ln(p_R) - \ln(1-p_R)))$$

where $p_D = 0.9, p_R = 0.6$

- (e) Given the previous odds ratio, derive the probability expressing how much more likely the doctor is to make the correct classification compared to the resident.

Ans:

Since the ratio is 6, it is 5 times more likely for the doctor to make the correct classification compared to the resident.

2. Problems for the maximum likelihood estimate and the maximum a posteriori estimate:

- (a) Assume $p(y | x) = N(ax, s^2)$, where all quantities are scalars and where a and s are known constants. You observe y_1, \dots, y_N . Derive the maximum likelihood estimate (MLE) of x .

Ans:

let $\mu = ax$, then $L(\mu, s^2) = \prod_{i=1}^N f(y_i; \mu, s^2) = (\sqrt{2\pi})^{-N} \exp[-\frac{1}{2s^2} \sum_{i=1}^N (y_i - \mu)^2]$

Thus, $\log L(\mu, s^2) = -\frac{N}{2} \log s^2 - \frac{N}{2} \log(2\pi) - \frac{\sum (y_i - \mu)^2}{2s^2}$

Set $\frac{\partial}{\partial \mu} \log(L(\mu, s^2)) = 0 = 2 * \frac{\sum (y_i - \mu)}{2s^2}$.

Therefore, $\mu_{MLE} = \bar{y}$, and $x_{MLE} = \frac{\bar{y}}{a}$

- (b) Assume $p(y | x) = N(ax, s^2)$, where all quantities are scalars, a and s are known constants, and the prior distribution over x is $N(m, r^2)$, where m and r are known constants. The *maximum a posteriori (MAP)* estimate is the value of x that maximizes $P(x|y) = P(y|x)P(x)/P(y)$. You observe y_1, \dots, y_N . Derive the maximum a posteriori estimate of x .

Ans:

let $\mu = ax$, then $\arg\max_x P(x|y) = \arg\max_x P(y|x) \frac{P(x)}{P(y)}$

$= \arg\max_x P(y|x)P(x) = \arg\max_x \log P(y|x)P(x)$

$\log P(y|x)P(x) = -\frac{N}{2} \log s^2 - \frac{N}{2} \log(2\pi) - \frac{\sum (y_i - \mu)^2}{2s^2} - \frac{1}{2} \log r^2 - \frac{1}{2} \log(2\pi) - \frac{(\mu - m)^2}{2r^2}$

Set $\frac{\partial}{\partial \mu} \log(\log P(y|x)P(x)) = 2 \frac{\sum (y_i - \mu)}{2s^2} - \frac{\mu - m}{r^2}$. Thus we get $\mu = \frac{N\bar{y}r^2 + ms^2}{Nr^2 + s^2} / a$

- (c) Assume that $a = 2$, $s = 3$, $m = 1$, and $r = 0.5$, and that you observed y values of -0.85, 0.68, -1.26, 2.36, 1.27, -3.49, -0.54, and 0.12. What are the maximum likelihood and maximum a posteriori estimates of x ? Explain the difference you observe between x_{MLE} and x_{MAP} ?

Ans:

$x_{MLE} = \frac{\bar{y}}{a} = -0.107$

$x_{MAP} = \frac{N\bar{y}r^2 + ms^2}{Nr^2 + s^2} / a = 0.39$

MLE selects the parameter that forms the most likelihood, whereas MAP uses bayesian, in which the prior parameter would be formatted to reflect the understanding of data's prior knowledge. Then the prior parameter will be adjusted accordingly to the new data, and produces the posterior. Therefore, such posteriors are data dependent and can vary.

3. Recall in class, we learned the form of a linear classifier as $f(\mathbf{x}; \mathbf{W}) = \mathbf{W}\mathbf{x} + \mathbf{b}$. In order to learn the parameters, we need to perform error-backpropagation, a way to compute partial derivatives (or gradients) w.r.t. the parameters of a neural network. Here, we are interested in the derivative of the softmax loss for a multinomial classification problem.

Let's first define the notations:

input features : $\mathbf{x} \in \mathbb{R}^D$.

target labels : $\mathbf{y} \in \mathbb{R}^K$.

multinomial linear classifier : $\mathbf{f} = \mathbf{W}\mathbf{x} + \mathbf{b}$, $\mathbf{W} \in \mathbb{R}^{K \times D}$ and $\mathbf{f}, \mathbf{b} \in \mathbb{R}^K$

e.g., for the k-th classification : $f_k = \mathbf{w}_k^T \mathbf{x} + b_k$, corresponding to y_k ,

where \mathbf{w}_k^T is the k-th row of \mathbf{W} , $k \in \{1 \dots K\}$

- (a) Please express the softmax loss of logistic regression, $L(\mathbf{x}, \mathbf{W}, \mathbf{b}, y)$ using the above notations.

$$L = -\log(\text{softmax}) = -\log\left(\frac{e^{f_i}}{\sum_{j=1}^K e^{f_j}}\right) = -\log\left(\frac{e^{\mathbf{w}_i^T \mathbf{x} + b_i}}{\sum_{j=1}^K e^{\mathbf{w}_j^T \mathbf{x} + b_j}}\right)$$

- (b) Please calculate its derivative Jacobian $\frac{\partial L}{\partial \mathbf{w}_k}$.

$$\frac{\partial L}{\partial \mathbf{w}_k} = -\frac{\partial}{\partial \mathbf{w}_k} \left(\log\left(\frac{e^{\mathbf{w}_i^T \mathbf{x} + b_i}}{\sum_{j=1}^K e^{\mathbf{w}_j^T \mathbf{x} + b_j}}\right) \right) = -\frac{\partial}{\partial \mathbf{w}_k} (\mathbf{w}_i^T \mathbf{x} + b_i) + \frac{\partial}{\partial \mathbf{w}_i} (\log(e^{\mathbf{w}_i^T \mathbf{x} + b_i}))$$

if $k = i$:

$$= -\mathbf{x} + \mathbf{x} * \frac{e^{\mathbf{w}_k^T \mathbf{x} + b_k}}{\sum_{j=1}^K e^{\mathbf{w}_j^T \mathbf{x} + b_j}}$$

else:

$$= \mathbf{x} \frac{e^{\mathbf{w}_k^T \mathbf{x} + b_k}}{\sum_{j=1}^K e^{\mathbf{w}_j^T \mathbf{x} + b_j}}$$

4. Direction of KL divergence. In many real-world applications, we often don't have full observation of the target distribution. Then it is important to determine the direction of KL

divergence when choosing it as an objective function. Here, we want to show the difference of KL divergence directions by calculating the gradient.

- (a) Show that KL divergence is asymmetric using the following example. We define a discrete random variable X . Now consider the case that we have two sampling distribution $P(x)$ and $Q(x)$, which we present as two hard encoded vector:

$$P(x) = [1, 6, 12, 5, 2, 8, 12, 4]$$

$$Q(x) = [1, 3, 6, 8, 15, 10, 5, 2]$$

Please compute 1) discrete probability distribution, $p(x)$ and $q(x)$. (hint: calculate the normalization). 2) two directions of KL divergence, $\mathbf{KL}(p||q)$ and $\mathbf{KL}(q||p)$.

1)

Ans:

$$p(x) = [0.02, 0.12, 0.24, 0.1, 0.04, 0.16, 0.24, 0.08]$$

$$q(x) = [0.02, 0.06, 0.12, 0.16, 0.3, 0.2, 0.1, 0.04]$$

2)

Ans:

$$\mathbf{KL}(p||q) = \sum_{x \in \mathcal{X}} p(x) \log\left(\frac{p(x)}{q(x)}\right) = 0.35$$

$$\mathbf{KL}(q||p) = \sum_{x \in \mathcal{X}} q(x) \log\left(\frac{q(x)}{p(x)}\right) = 0.48$$

- (b) Next, we try to optimize a model to fit the target distribution. We hope to pay attention to the issue of normalization and see what elements are involved in each direction.

Note that p and q_θ are probability distributions. To simplify expression, $p(d)$ and $q(d)$ are all discrete variables, where $p(d) = P(d)/Z_p$, Z_p is normalization factor. $p(d)$ is regarded as the target distribution, and we optimize θ to fit model distribution $q_\theta(d)$ to $p(d)$. Please express $\mathbf{KL}(q_\theta||p)$ and $\mathbf{KL}(p||q_\theta)$ as optimization objective functions. (hint: remove all constant items that are not related to the optimization process)

Ans:

$$\underset{\theta}{\operatorname{argmin}} \mathbf{KL}(p||q_\theta)$$

, or

$$\underset{\theta}{\operatorname{argmin}} \mathbf{KL}(q_\theta||p)$$

- (c) Can you tell which direction is easier for computation? Why? Then please calculate the gradient of $\mathbf{KL}(q_\theta||p)$ and $\mathbf{KL}(p||q_\theta)$ w.r.t. $q_\theta(d)$ using the results in (b).

Ans:

$\mathbf{KL}(p||q_\theta)$ is the easier direction for computation, since when taking the derivative with respect to q_θ , q will only be calculated once.

$$\frac{\partial}{\partial q_\theta(d)} \mathbf{KL}(p||q_\theta) = - \sum_{x \in \mathcal{X}} \frac{p(x)}{q_\theta(x)}$$

5. In this problem, you are provided an opportunity to perform hands-on calculation of the SVM loss and softmax loss we learned in class.

We define a model of Linear Classifier:

$$f(\mathbf{x}, \mathbf{W}) = \mathbf{W}\mathbf{x} + \mathbf{b}$$

Giving a data sample:

$$\mathbf{x}_i = \begin{bmatrix} -15 \\ 22 \\ -44 \\ 56 \end{bmatrix}, y_i = 2$$

At one iteration, we have

$$\mathbf{W} = \begin{bmatrix} 0.01, & -0.05, & 0.1, & 0.05 \\ 0.7, & 0.2, & 0.05, & 0.16 \\ 0.0, & -0.45, & -0.2, & 0.03 \end{bmatrix}, \mathbf{b} = \begin{bmatrix} 0.0 \\ 0.2 \\ -0.3 \end{bmatrix}$$

Please calculate 1) SVM Loss (hinge loss) and 2) softmax loss (cross-entropy loss) of this sample point.

Ans:

1)

$$f(\mathbf{x}_i, \mathbf{W}) = \mathbf{W}\mathbf{x}_i + \mathbf{b} = \begin{bmatrix} -2.85 \\ 0.86 \\ 0.28 \end{bmatrix}$$

$$L_i = \sum_{j \neq y_i} \max(0, s_j - s_{y_i} + 1) = \max(0, -2.85 - 0.28 + 1) + \max(0, 0.86 - 0.28 + 1) = 1.58$$

2)

$$\text{softmax}(\mathbf{x}_i) = -\log \frac{e^{0.28}}{e^{0.86} + e^{-2.85} + e^{0.28}} = 1.04$$
